Editor: Michael T. Dunn

Premise of research. This study describes a new fossil species of *Bowenia* and reconsiders known fossil species and their evolutionary significance.

Methodology. The fossils we describe here were collected for this study or were available from previous collections made over several decades. The fossils were identified by direct comparisons with extant and fossil species.

Pivotal results. A reexamination of known and newly discovered *Bowenia* macrofossils confirms the presence of at least three fossil species in Australia. A new species, *Bowenia johnsonii*, is described from the southernmost location, the Early Eocene Lowana Road site in southwest Tasmania. When compared with the two extant species, the three fossil species demonstrate two distinct pinnule morphologies: relatively small with distinct serrations in *Bowenia eocenica* and *Bowenia papillosa* and larger pinnules with minute serrations in *B. johnsonii*. When considered together, the stomata of the extant species are denser and larger than those of the fossil taxa.

Conclusions. The cycad genus *Bowenia* has a restricted extant distribution along the east coast of Queensland but is known more widely within Australia from fossils. The fossil record of *Bowenia* is important in documenting the past distribution of this genus, and aspects of its pinnule morphology provide insights into its environmental interactions. The possible relationship of the fossil *Bowenia* species with the Aptian Argentinian genus *Eobowenia* is considered, along with some fragmentary Australian fossils of probable *Bowenia*.

Keywords: cycads, Zamiaceae, *Bowenia*, Eocene, Australia.

Introduction

Cycads comprise a small but important part of the living Australian flora, but the fossil record of the extant genera is relatively sparse (Hill 1998a). *Bowenia* is an endemic Australian cycad genus, restricted to two extant species, *Bowenia spectabilis* Hook. ex Hook.f. and *B. serrulata* (W. Bull.) Chamberlain, both of which are found in small areas of near-coastal Queensland in northeast Australia (fig. 1). Both species are low-statured understory plants with a subterranean stem (Chamberlain 1912), but whereas *B. spectabilis* occurs in wet tropical rain forest, *B. serrulata* occurs in a more seasonally dry climate and is often found in eucalypt woodlands, most commonly near water bodies (Wilson 2004). The published fossil record of *Bowenia* consists of pinnule fragments from several Eocene sites in eastern and central Australia (fig. 1), including two named species, *Bowenia eocenica* R.S. Hill from Anglesea and *Bowenia papillosa* R.S. Hill from Nerriga (Hill 1978).

¹ Author for correspondence; email: bob.hill@adelaide.edu.au.

Bowenia has a long history of uncertain familial placement within the cycads, having been variously assigned to Zamiaceae, Stangeriaceae, and the monotypic Boweniaceae, based on its comparative morphology. Several molecular phylogenies of cycads have been published (e.g., Treutlein and Wink 2002; Hill et al. 2003; Bogler and Francisco-Ortega 2004; Chaw et al. 2005; Zgurski et al. 2008; Salas-Leiva et al. 2013; Condamine et al. 2015), and the consistent finding is that only two families can be recognized with confidence, the Cycadaceae, containing the single genus *Cycas*, and the Zamiaceae, containing all other genera. Based on molecular evidence, *Bowenia* appears to be somewhat isolated from the other cycads, with a stem extending to the Cretaceous (Nagalingum et al. 2011; Salas-Leiva et al. 2013).

The purpose of this article is to reexamine the species originally published by Hill (1978) and specimens from several other localities that have not previously been examined in detail to determine what they reveal about the evolution of this highly distinctive genus and its place in the broader Australian vegetation. Furthermore, the preservation of most of the fossils allows a detailed examination of the pinnule and stomatal morphology and an assessment of the environments inhabited

by these fossil species when they were alive. The recent description of Aptian fossils from Argentina assigned to *Eobowenia* (Coiro and Pott 2017) is also considered, since it is probably the most closely related fossil taxon to *Bowenia*.

Material and Methods

Extant Specimens

Bowenia serrulata occurs near Gladstone in Queensland and *Bowenia spectabilis* occurs in northeast Queensland in areas surrounding Cairns (fig. 1). Five *B. spectabilis* specimens were collected from Butchers Creek in the Atherton Tablelands in Queensland (lat. 17°32'S, long. 145°69'E) directly for this study, and 35 specimens of *B. spectabilis* and 13 of *B. serrulata* were provided by the Queensland Herbarium (BRI), National Herbarium of Victoria (MEL), and Australian Tropical Herbarium (QRS).

Preparation of Cuticles of Extant Specimens

Cuticles were prepared using standard techniques. Most often, 1-cm² pieces of pinnule were cut from the margin halfway along the lamina. Pinnule pieces were placed into test tubes and covered in 80% ethanol v/v overnight. The ethanol was then replaced with a 2:1 solution of 35% w/v hydrogen peroxide and 80% ethanol v/v and gently heated until the pinnule pieces turned

translucent. The pinnule pieces were then rinsed with reverse-osmosis (RO) water and placed under a dissecting microscope so that debris could be brushed away from the cuticle, which was then rinsed with RO water. Cuticles were then stained with crystal violet and mounted on slides in phenol glycerine jelly.

Fossil Localities

New material and previously described or reported specimens were available from several sites.

Nerriga

The Nerriga locality is about 90 km east-northeast of Canberra in the southern tablelands of New South Wales (fig. 1). The fossil-bearing sediments are considered to be about 45 Myr old, which is close to the Early–Middle Eocene boundary (table 1). The macrofossil flora at Nerriga has been described as representing simple notophyll vine forest (Christophel 1980) as defined by Webb (1959). It is dominated by angiosperms, with several species of large and broad-leaved Lauraceae (Hill 1986), in conjunction with a common large-leaved Menispermaceae species attributed to a vine (Hill 1989) and several other entire- or serrate-margined leaf taxa (Hill 1982), along with the tropical Casuarinaceae genus *Gymnostoma* (Christophel 1980). The extinct cycad genus *Pterostoma*

has also been recorded at Nerriga, as well as a fossil species of the extant cycad genus *Lepidozamia* (Hill 1980).

Anglesea

The Anglesea coal mine is about 3 km northwest of the coastal town of Anglesea in Victoria (fig. 1), and the fossil-bearing sediments are considered to be of late Middle Eocene age (table 1). These sediments sit above the main coal seam as clay and clay sand lenses. The exact stratigraphic positions of the various lenses is unknown (Christophel et al. 1987). The macroflora at Anglesea is also dominated by angiosperms, but nonangiosperms include common fragments of the extinct cycad *Pterostoma* (Hill 1980) and several species and genera within the conifer family Podocarpaceae (Greenwood 1987; Hill and Scriven 1998). Angiosperm remains are very well preserved and diverse and include *Gymnostoma* (Casuarinaceae; Christophel 1980), Ebenaceae (Basinger and Christophel 1985), several Lauraceae species (Christophel et al. 1987), Proteaceae (Christophel 1984; Hill and Christophel 1988; Carpenter et al. 2016), Myrtaceae (Christophel and Lys 1986), and many other unidentified taxa. Christophel et al. (1987) regarded the Anglesea vegetation as being closest to extant Complex Mesophyll Vine Forest and considered that its composition and structure was similar to that of the vegetation at modern Noah Creek in northeast Queensland.

Maslin Bay

The Maslin Bay locality is also now near coastal, about 35 km south of Adelaide in South Australia (fig. 1). The fossils were preserved within a single carbonaceous clay lens in the North Maslin Sands (Christophel and Blackburn 1978) that are considered to have formed in the early Middle Eocene (table 1). The Maslin Bay macroflora is highly diverse and dominated by broad-leaved angiosperms (Christophel 1994). Rare ferns (*Lygodium*; Rozefelds et al. 1992) and conifers, including *Agathis* in the Araucariaceae (Christophel and Blackburn 1978) and *Willungia* in the Podocarpaceae (Hill and Pole 1992), have been recorded. Several broad-leaved angiosperm taxa have been identified, including extinct genera of the Proteaceae (Blackburn 1981; Carpenter et al. 2006, 2016), *Ceratopetalum* (Cunoniaceae; Barnes and Hill 1999), and a deciduous leaved *Notho-*

fagus species (Nothofagaceae; Scriven et al. 1995). Many other taxa have been reported (e.g., *Brachychiton*, up to five Myrtaceae taxa, Ebenaceae, see Scriven 1993) but have not been formally described. *Gymnostoma* (Casuarinaceae) is also common (Christophel 1994). The flora as a whole has been compared with modern Complex Notophyll Vine Forest (Greenwood 1994).

Rundle Formation and Biloela Basin Sediments

The Rundle Oil Shale (Rundle Formation, Narrows Graben) occurs ~25 km northwest of Gladstone in Queensland (fig. 1) and contains diverse but fragmented plant macrofossil remains (Rowett 1988), which are regarded as being most probably of Late Eocene age (table 1). The macroflora at Rundle is so far known only from dispersed cuticle, where diversity is high, angiosperms dominate, and Lauraceae is the prominent family (Christophel 1989).

New fossiliferous material from the Biloela Formation of the Biloela Basin west of Gladstone was collected for the current study from the Zillmere Exploration Data Centre of the Geological Survey of Queensland. This basin is proximal to the Narrows Graben, and the Rundle and Biloela Formation sediments discussed here are probably palynostratigraphically contemporaneous (table 1). New samples of dispersed cuticle were recovered from borehole GSQ Monto 5, which contains the type section of the Biloela Formation (Noon and Grimes in Noon 1982). Similar to the Rundle shale sediments, Lauraceae cuticles were abundant in Monto 5 (Macphail et al. 2014).

Lowana Road

The Lowana Road sediments are part of widespread and thick Early Eocene (table 1) sediments that occur in the Strahan region of Macquarie Harbour in southwest Tasmania (fig. 1). The Lowana Road fossil flora is a discrete assemblage within this general region and was derived from estuarine vegetation growing in a warm to hot and wet climate (Carpenter et al. 2012). A regional Early Eocene flora was reported by Pole (2007) from dispersed cuticular remains. Mangrove species (e.g., the southernmost record of the mangrove palm genus *Nypa*; Pole and Macphail 1996) occur widely, and the

Lowana Road assemblage also includes an extinct seed fern (McLoughlin et al. 2008), *Lygodium* (Rozefelds et al. 2017), and probable rainforest angiosperms (Carpenter et al. 2007; Conran et al. 2009). Conifer fossils are diverse and common regionally, and they include representatives of the Araucariaceae (Bigwood and Hill 1985; Hill and Bigwood 1987; Hill 1990), Cupressaceae (Paull and Hill 2009), and Podocarpaceae (Wells and Hill 1989; Hill and Carpenter 1991).

Other specimens considered here relied on published information and not direct observation of specimens. All localities are listed in table 1.

Fossil Specimens

The fossil pinnules from Nerriga and Anglesea are mummified and could be retrieved more or less complete from the encasing sediments. This was done by soaking sediment blocks in dilute aqueous hydrogen peroxide that was gently heated to dissociate the sediments, which were then sieved to retrieve the macrofossils. Individual specimens were gently brushed clean and photographed using transmitted light to best show the venation patterns. The Lowana Road specimens were too fragmentary to be removed from the encasing sediments. Large blocks of sediment were split along bedding planes to reveal pinnule remains, often with the venation preserved as impressions in the sediment and with large pieces of the organic remains of the pinnules still attached. Sediment impressions were photographed using low-angle reflected light to best highlight the venation pattern and pinnule margins.

Cuticle slides of six *Bowenia eocenica* specimens from the Anglesea site were borrowed from Melbourne Museum. Cuticle slides of the Lowana Road specimens were prepared by soaking organic pinnule fragments in 5% aqueous chromium trioxide solution until all organic matter except the cuticle had dissolved. The cuticle was then rinsed in distilled water, cleared briefly in 2% aqueous ammonia solution, rinsed again, and stained with safranin O. Cuticles were then mounted on microscope slides in phenol glycerine jelly. Some unstained cuticles were attached to aluminium stubs with double-sided adhesive and coated with a gold-carbon mix. They were examined with an XL30 scanning electron microscope (Philips, Amsterdam) operated at 10 kV.

Rundle and Maslin Bay specimens consisted of dispersed cuticle only and were available from existing collections that formed the basis of detailed studies by Rowett (1988) and Scriven (1993), respectively. The cuticle slides form part of the David T. Blackburn Palaeobotany Collection at the University of Adelaide. Cuticles were rephotographed using an Olympus AX70 compound microscope fitted with an Olympus UC50 digital camera. Fragments of *Bowenia* cuticle from the Biloela Basin were recovered by sieving from associated sediments and prepared as for the Lowana Road cuticles.

The holotype, and only specimen of *B. papillosa*, was retrieved from the South Australian State Herbarium, where it is stored. Unfortunately, the accompanying cuticle slide could not be located, so a new cuticle slide was prepared from the remaining pinnule fragments. Observations made here came from this new slide, the existing published images, and some extra photographs that were not published in the original article (Hill 1978).

Results

Fossil Identification

The pinnule fossils from Nerriga and Anglesea have previously been described as species of *Bowenia* (Hill 1978). *Bowenia* pinnules have very distinctive serrate or entire margins and simple dichotomously branching venation without anastomoses. When serrations are present, they are the termination point for veins; in entire-margined pinnules, veins terminate at the margin without forming a serration. Thomas and Bancroft (1913) noted that *Bowenia* pinnules are amphistomatic but with significantly fewer stomata on the adaxial surface. They also recorded the guard cells as being situated practically at the level of the epidermis and less sunken than in any other cycad genus except *Stangeria*. Pant and Nautiyal (1963) added to this description by noting that rounded or oval hair scars are usually present above and between the veins on the abaxial surface and along the pinnule margins. According to Greguss (1968), *Bowenia* can be readily distinguished from other extant cycad genera because it has stomata scattered on the upper pinnule surface (2–5 stomata mm⁻²) and grouped in bands on the lower surface (55–60 stomata mm⁻²). Also, in comparison with other cycads, the epidermal cell walls are mostly thin.

Given the combination of characters listed above, assigning a fossil to *Bowenia* should be relatively straightforward, provided a pinnule or a significant fragment of one is preserved and cuticle morphology is well preserved. This is the case for fossils from Nerriga, Anglesea, and Lowana Road. The fossils from Maslin Bay, Rundle, and the Biloela Basin consist of dispersed cuticle only. The Rundle dispersed cuticle fragments are quite common and include some with margins attached and serrations sometimes present. A combination of the cuticular morphology, presence of serrations, and veins that terminate in them mean that these fossils can be assigned to *Bowenia* with confidence. The Maslin Bay taxon is represented by rare fragments of dispersed cuticle. While this cuticle is consistent with *Bowenia*, no pinnule margins have been recovered and assignment to the genus is less certain. However, the cuticular morphology of this taxon is consistent with *Bowenia* and matches no other extant cycad. The same justification applies for the Biloela Basin specimens. The generic identification of these specimens has been complicated by the recent description of the fossil cycad genus *Eobowenia* by Coiro and Pott (2017). The significance of this genus is considered in detail later.

Reconsideration of the Previously Described Species

Bowenia papillosa

Hill (1978) described *B. papillosa* from the basal half of a single pinnule and the rachis to which it was attached. This exceptionally well-preserved fossil was assigned to a new species of *Bowenia* because of the presence of unicellular papillae, which occur over the veins, more commonly on the upper than on the lower pinnule surface. The other notable feature of this fossil is the clear preservation of numerous dichotomously branching veinlets arising from the veins. In reconsidering this specimen, it was noted that in the original illustra-

tion of the specimen (fig. 2 in Hill 1978) the pinnule and rachis, which were separated from each other during recovery of the fossil from the sediment, were almost certainly illustrated the wrong way around. In all living *Bowenia* specimens examined, the lateral pinnules are asymmetrical, with the more convex margin being on the apical side of the whole leaf. The *B. papillosa* specimen illustrated by Hill (1978) has

the convex side presented toward the base. That has been corrected in the illustration of this specimen here (fig. 2B). This specimen is smaller than pinnules of either of the extant species (table 2; fig. 2A), although some *Bowenia serrulata* pinnules overlap this size range. *Bowenia papillosa* also has distinctly smaller and less dense stomata than either of the extant species (table 2).

Fig. 2 Pinnules of extant and fossil *Bowenia*. A, *Bowenia serrulata*, cleared pinnule of the extant species, showing the serrate margin and dichotomously branching veins that all arise from the pinnule base. All veins terminate in serrations. B, Holotype and only specimen of *Bowenia papillosa* from Nerriga (N-0114), with the basal half of a single pinnule preserved. The attachment of the pinnule to the rachis is in the opposite direction to that figured in Hill (1978) and more likely reflects the orientation of the pinnule. Venation is very similar to that of *B. serrulata*, with veins terminating in serrations. C–H, Specimens of *Bowenia eocenica* from Anglesea (C = AN2293, D = ANb3000, E = AN2167, F = 2172/2094, G = ANb3001, H = P52689a). The venation is very similar to *B. serrulata*, except that in each specimen there is a rudimentary midvein at the base of the pinnule that extends for up to one-quarter of the length of the pinnule. Veins terminate in serrations. H is the holotype of this species. I–K, Specimens of *Bowenia johnsonii* from Lowana Road, including the holotype I (I = LO-4, J = LO-5, K = LO-7). Venation is very similar to *B. serrulata*, with veins terminating in very small serrations. Scale bars = 0.5 cm.

Table 2

Mean Pinnule Size and Stomatal Traits (\pm SD) of All *Bowenia* Species Considered

Species	Pinnule area (mm ²)	Serrations	Stomatal density, abaxial surface (stomata mm ⁻²)	Stomatal size (μ m ²)
<i>B. eocenica</i>	137 \pm 60	Intermediate	35 \pm 4	1246 \pm 187
<i>B. papillosa</i>	263	Intermediate	29 \pm 5	1390 \pm 83
<i>B. johnsonii</i>	1061 \pm 240	Small	35 \pm 11	1503 \pm 286
Maslin Bay	Unknown	Unknown	41 \pm 2	1588 \pm 154
Rundle	Unknown	Intermediate-large	44 \pm 4	1422 \pm 103
Bundey Basin	Unknown	Unknown	Unknown	1232 \pm 233
<i>B. serrulata</i>	1772 \pm 1129	Large	48 \pm 10	2010 \pm 321
<i>B. spectabilis</i>	2567 \pm 873	Absent or small	48 \pm 16	2003 \pm 338
<i>Eobowenia incrassata</i>	32 \pm 2	Disorganized	Unknown	1045 \pm 203

Note. Where the species name is uncertain, the fossil location is listed.

Bowenia eocenica

Bowenia eocenica was described from two small fragments of what was probably a single pinnule retrieved from the Anglesea sediments (Hill 1978). While these fragments are small, they preserve important parts of the pinnule, since one demonstrates that the margin is regularly serrate and the other shows what appears to be a rudimentary midvein at the base of the pinnule (fig. 2H), a feature otherwise not seen in the genus. The cuticle lacks the papillae of *B. papillosa* and this, along with the presence of the rudimentary midvein, justified its placement in a separate species. Since the publication of this species in 1978, thousands of mummified leaves, mostly angiosperms, have been collected from the Anglesea sediments and most are now housed at Melbourne Museum. Several nearly complete specimens of fossil *Bowenia* pinnules were retrieved during this process and available for this study.

With complete pinnules available, there are important features that can be considered in more detail. First, since all of these pinnules have a rudimentary midvein at the base of the pinnule, they belong to *B. eocenica* (fig. 2C–2H cf. fig. 2A). Second, it is clear that the pinnules of *B. eocenica* from Anglesea are smaller (in length, width, and area) than those of either of the extant species (table 2), although as with *B. papillosa*, there was some overlap with *B. serrulata*.

An examination of the cuticular morphology of new specimens of *B. eocenica* from Anglesea confirms the details of the original description. However, several trichome bases were observed, and in some cases what appears to be a basal cell of the trichome is also preserved (fig. 3A). These structures are different than the papillae described for *B. papillosa*. *Bowenia eocenica* has significantly smaller stomata than either of the extant species and also fewer per unit area (table 2).

Specimens from New Locations

Lowana Road

The Early Eocene Lowana Road sediments (fig. 1) have yielded a large number of complete and fragmentary pinnules (fig. 2I–2K). These pinnules are larger than those of the specimens from Nerriga and Anglesea, but on average they are smaller than either of the extant species, although they overlap the size range of both (table 2). They consistently lack a midvein, which separates them from *B. eocenica*, and no papillae have been ob-

served, which separates them from *B. papillosa*. They have the typical *Bowenia* stomatal morphology (fig. 3B). Rare trichome bases are preserved, but there is no evidence of the basal trichome cell that was present in some *B. eocenica* specimens. The scanning electron micrographs of this species show the very thin cuticle, including that around the stomata (fig. 3C, 3D). However, some epidermal cells have much thicker cuticle, which shows as a darker stained cell in the light micrographs (fig. 3B). An important feature of these pinnules is the size and shape of the serrations. While they are clearly present, they are relatively small and represent rounded indentations rather than the obvious and relatively large teeth of extant *B. serrulata* (fig. 4D cf. fig. 4A) or those of the two fossil species, *B. eocenica* and *B. papillosa* (fig. 4B, 4C). Some specimens of extant *Bowenia spectabilis* have serrations that are virtually identical to those of the Lowana Road specimens (fig. 4D cf. fig. 4E). This means that either the fossils represent *B. spectabilis*, or a new species should be established in recognition of the large spatial and temporal separations of fossil and extant specimens and the possibility that reproductive or other vegetative characters may have been distinct. We favor the latter option, given that all the fossil specimens examined are serrate, whereas serrate pinnules are rare in *B. spectabilis* (Johnson 1959; Wilson 2004), and the Lowana Road fossils have significantly smaller and less dense stomata than either of the extant species (table 2) and larger pinnules than *B. serrulata*. Therefore, we place the Lowana Road fossils in a new species of *Bowenia*, here named *B. johnsonii*.

Rundle/Biloela Basin

Dispersed cuticle fragments from the probable Late Eocene sediments at Rundle in Queensland (fig. 1) were identified as *Bowenia* by Rowett (1988). Rowett (1988) considered that papillae occur on at least some of the specimens, especially on the upper surface, and he hence assigned these specimens to *B. papillosa*. We had access to some but not all of Rowett's dispersed cuticle slides and new cuticle specimens of *Bowenia* from the Biloela Basin, which probably belong to the same taxon. Some possible papillae bases were observed (fig. 3E, although these may more plausibly be trichome bases without the basal cell preserved), as were trichome bases with the basal trichome cell in place (fig. 3F). This suggests an affinity with *B. papillosa*, but more complete specimens may lead to a different conclusion. Some specimens included fragments of the pinnule margin, confirming the presence of well-developed serrations at

Fig. 3 Light micrographs (LMs) and scanning electron micrographs (SEMs) of fossil *Bowenia* cuticles. A, LM of the adaxial pinnule surface of *Bowenia eocenica* from Anglesea, showing a trichome base with a cylindrical basal trichome cell (AN2094); scale bar = 120 μm . B, LM of the abaxial pinnule surface of *Bowenia johnsonii* from Lowana Road, showing stomata among characteristic cycad epidermal cells (LO-5). Note the darker staining epidermal cells, indicating thicker cuticle over those cells; scale bar = 100 μm . C, SEM of the abaxial pinnule surface of *B. johnsonii* from Lowana Road, showing the inner cuticular surface, with characteristic cycad stomata (LO-4). The cuticle has cracked over some cells where it is thicker, a state represented by the darker staining cells in the LMs; scale bar = 100 μm . D, SEM of the adaxial pinnule surface of *B. johnsonii* from Lowana Road, showing the inner cuticular surface, with characteristic cycad epidermal cells (LO-5). Note the cracking of the cuticle over cells where the cuticle is thicker, as in C; scale bar = 100 μm . E, LM of the adaxial pinnule surface of *Bowenia* from Rundle, showing two possible papillae surrounded by dark staining cells (R-007); scale bar = 50 μm . F, LM of the adaxial pinnule surface of *Bowenia* from Biloela Basin, showing a trichome base with a cylindrical basal trichome cell (R-005); scale bar = 25 μm .

least 2 mm long, similar to those seen in *B. serrulata*, and much larger than those in the single specimen of *B. papillosa* (fig. 4F cf. fig. 4A, 4B). Further specimens may show that this taxon is distinct from *B. papillosa* in having much larger serrations, possibly within the range of the extant species. Hence, these fragmentary specimens, while distinct from *Eobowenia* and clearly belonging to *Bowenia*, will not be assigned to a species until more complete specimens are obtained.

Maslin Bay

Dispersed cuticle fragments from the Middle Eocene Maslin Bay sediments were assigned to *Bowenia* by Scriven (1993). Her slides were available to us, and we found a small number of fragmentary specimens consistent with *Bowenia*. However, no trichome bases or papillae were observed and no margin is preserved, so these specimens remain identified at the generic level only, and even that is not certain given the cuticular morphology of *Eobowenia* (see “Discussion”).

Other Specimens

Four other possible records of *Bowenia* deserve brief consideration. Carpenter et al. (2015) described a Late Campanian-Maastrichtian flora from the Bunday Basin, which is ~140 km northeast of Alice Springs in the Northern Territory (fig. 1). The diverse dispersed cuticle macroflora described includes one

specimen (their Fig. 7F) that they described as “?*Bowenia*.” This cuticle fragment contains several stomata and is completely consistent with extant *Bowenia*, but they are also very similar to *Eobowenia*. The stomatal size of this specimen is close to that of all fossil *Bowenia* species (table 2). This represents the oldest known fossil record of the *Bowenia* lineage in Australia, but the fragmentary nature of the cuticle precludes it being assigned to a species. Hill (1998b) reported *Bowenia* from the Regatta Point site near Strahan in southwestern Tasmania (fig. 1), and Pole (2007) assigned dispersed cuticle specimens from sediments in the region to *B. eocenica*, despite the diagnosis for that species requiring details of pinnule morphology (Hill 1978). Here we regard all these fossils as probably belonging to *B. johnsonii*, noting that Early Eocene sediments are widespread in the Strahan region and that there appear to be many other fossil taxa in common between the Lowana Road assemblage and Regatta Point. Rowett (1998) recorded dispersed cuticle of *Bowenia* from the early Middle Eocene North Maslin Sands at One Tree Hill in South Australia (fig. 1). While this taxon was not illustrated, it may have been conspecific with the specimens recorded from the contemporaneous and geographically proximal Maslin Bay locality (see above). Carpenter et al. (2011) described a single specimen from the possibly latest Oligocene to mid-Late Miocene sediments at Lightning Ridge (fig. 1) as “?*Bowenia*,” stating that the specimen “could be interpreted as the base of an apparently robust pinna fragment showing stout, occasionally dichotomising veins arising from a constricted base and lacking a midvein.”

Fig. 4 Details of the margin of fossil and living *Bowenia* species. *A*, *Bowenia serrulata*, showing well-developed serrations with a vein terminating in each. *B*, *Bowenia papillosa* from Nerriga (N-0114), showing a well-developed serration, which is smaller than most of those of *B. serrulata*, but approximately in proportion to the difference in pinnule size. *C*, *Bowenia eocenica* (AN2293), showing well-developed serrations that are similar in size to those of *B. papillosa*. *D*, *Bowenia johnsonii* (LO-5), showing very small and rounded serrations that are quite distinct from all the other fossil species. *E*, *Bowenia spectabilis*, a rare specimen with serrations that are small and rounded and almost identical to those of *B. johnsonii*. *F*, *Bowenia* from Rundle (after Rowett 1988). Note the relatively large size of this serration, which is very similar to those of *B. serrulata*. Scale bars = 1 mm.

This specimen is very similar to both fossil and extant pinnules of *Bowenia* in its size, shape, and venation, and is very likely to represent a fossil occurrence of the genus, but the lack of cuticle preservation and of a margin to the pinnule precludes a definite identification. Finally, Wilson (2004) noted a Miocene occurrence of *Bowenia* at Baralaba in central Queensland (fig. 1), but in the absence of illustrations or any other confirmation of the record, this is not considered further here.

The Significance of *Eobowenia*

Coiro and Pott (2017) described the new fossil genus, *Eobowenia*, from the Aptian locality at Estancia Bajo Grande, Santa Cruz Province, Argentina. The cuticle morphology of *Eobowenia* is very similar to extant *Bowenia*, and in the absence of

sufficiently complete and well-preserved pinnules of the former, it may be impossible to separate the two genera. The single species of *Eobowenia*, *Eobowenia incrassata*, is described as having pinnate leaves with leaflets subopposite and with a broad base and serrate margins. A delicate midvein is reported, but the evidence for this is sparse (fig. 5A, 5B).

The specimen illustrated by Coiro and Pott (2017; fig. 5B) is listed as the epitype, and they did not illustrate the holotype, which was originally described as *Almargenia incrassata* by Archangelsky (1966). The illustration in Archangelsky's article is not high quality by today's standards, but we were able to source a high-quality image of the holotype courtesy of S. Archangelsky and L. C. A. Martínez (fig. 5A). Artabe and Stevenson (1999) also illustrated this species (their fig. 2C, reinterpreted here as fig. 5C), and while there is no scale bar, the specimen is

Fig. 5 Illustrations of *Eobowenia incrassata*. A, Holotype, showing the apex of the leaf (top right), with a poorly defined and lobed terminal pinna and with several pinnae arising from the main leaf axis below this. The attachment of each pinna is broad but is considerably narrower than the widest part of the pinna. These pinnae appear to have poorly defined lobes or teeth; scale bar = 5 mm. B, Drawing of the isotype of *E. incrassata*, showing some of the poorly preserved veins. There may be evidence of a midvein here, but it is not compelling. Redrawn from Coiro and Pott (2017); scale bar = 5 mm. C, Drawing of part of a leaf of *E. incrassata*, showing the middle portion of the leaf, with relatively well-defined pinnae that have broad attachments at the base, probably broader than that observed in the holotype. This specimen is redrawn from Artabe and Stevenson (1999). No scale bar was provided, and the original of this specimen has not been located. It is shown here with an estimated size based on 5B, but this is probably at the lower end of the potential size range.

informative in appearing to represent pinnae from the middle of a leaf.

It is possible that *E. incrassata* has a close relationship with *Bowenia* (Coiro and Pott 2017), but if so, some significant changes in leaf morphology in *Bowenia* took place in the ~65 Myr prior to the Early Eocene. However, it is clear that if fossils are found with cuticular morphology preserved, but with little detail of the whole pinna, then these fossils probably cannot be assigned with certainty to either *Eobowenia* or *Bowenia*.

Systematics

Order—Cycadales E. Pfitzer. *Ubersicht der Naturlichen Systems der Pflanzen*. 28. 1898.

Family—Zamiaceae P.F. Horaninow. *Prima Lineae Systemis Naturae*. Sty. Petersburg. 1834.

Genus—*Bowenia* Hook. ex Hook.f.

Species—*Bowenia johnsonii* R.S.Hill, K.E.Hill, Carpenter et Jordan sp. nov. (Figs. 2L–2K, 3B–3D, 4D)

Diagnosis. *Bowenia* fossils without evidence of reproductive structures. Pinnules 94 (77–104) mm long, 29 (21–34) mm wide, midvein absent, veins terminating in small rounded teeth. Trichome bases rare on epidermis, papillae absent.

Etymology. Named in memory of Dr. L.A.S. Johnson, who wrote the seminal work on Australian cycads.

Holotype. LO-4, stored at the School of Biological Sciences, University of Tasmania.

Repository. School of Biological Sciences, University of Tasmania.

Type locality. Lowana Road, southwestern Tasmania (lat. 42°11'S, long. 145°22'E).

Comparison of Fossil and Living Species

Of the two extant species, *Bowenia spectabilis* has the largest pinnules, and these are usually entire-margined, except for occasional specimens in more open vegetation that bear small, or sometimes large, serrations (Wilson 2004). *Bowenia serrulata* has, on average, significantly smaller pinnules than *B. spectabilis* (table 2) and consistently much more prominent serrations, and it also occurs in more open vegetation and in a generally warmer and drier climate than *B. spectabilis* (Wilson 2004). Two of the fossil species, *B. eocenica* and *B. papillosa*, have small pinnules with serrations of intermediate size and low stomatal density and size compared with the other fossil and extant species (table 2). *Bowenia johnsonii* has significantly larger pinnules than *B. eocenica* but has smaller serrations and a low stomatal density and size that are similar to *B. eocenica* and *B. papillosa*.

The common trichome type in *Bowenia* is typical of cycads in having a thickened complex base and a basal trichome cell that is cylindrical and terminates presumably where another trichome cell was once attached (fig. 3A, 3F). This trichome structure is common in the Zamiaceae (Stevenson 1981) and has been illustrated by, for example, Acuña-Castillo and Marín-Méndez (2013) from *Zamia* (now *Chigua*) *restrepoi*. The papillae in *B. papillosa* have not been recorded in other cycads.

One of the most distinctive features of the fossil *Bowenia* species is the rudimentary midvein in *B. eocenica*. Hill (1978) noted this feature in the pinnule fragment he described, stating that the “dichotomously branching veins arise alternately at the base of the pinnule over a greater distance than in the other species and the central vein gives the appearance of a midvein.” This rudimentary midvein occurs in every *B. eocenica* pinnule (fig. 2C–2H) but is absent from all other fossil and living *Bowenia* species examined. Midveins are a striking feature of *Cycas* species, but they also occur in some Zamiaceae species. Stevenson et al. (1996) concluded that there are two types of

midvein in cycads: “a simple mid-vein composed of a single vein (e.g., *Cycas*) and a compound mid-vein composed of two or more veins (e.g., *Stangeria*.” They also noted the presence of compound midveins in the extant genus *Chigua*, and perhaps the closest to the situation seen in *B. eocenica* among the extant Zamiaceae species is in *Chigua restrepoi* (Stevenson 1990; fig. 6A). In this species a clearly defined midvein extends for about two-thirds of the length of the pinnule, with side branches occurring at high angles, sometimes branching dichotomously, before every vein ends in a serration. This venation pattern is very similar to that of *B. eocenica*, except that in the latter the midvein extends only about one-quarter of the length of the pinnule before disappearing among high-angle dichotomously branching veins that all terminate in serrations (fig. 6B). *Bowenia eocenica* is intermediate between the pattern seen in *C. restrepoi* and *B. serrulata* (fig. 6B cf. fig. 6A, 6C). Part of a fossil pinnule

that has very similar venation to *C. restrepoi*, but with an even more robust midvein, has been recovered from Early Cretaceous sediments in Patagonia (Passalia et al. 2010; fig. 6D), showing that a strong midvein in pinnules was present in Gondwanan cycads long before *B. eocenica* was growing in southeastern Australia. As noted above, *Eobowenia incrassata* is described as having a delicate midvein (Coiro and Pott 2017), but the evidence for this is not compelling (fig. 5B) and is well short of the midvein in *B. eocenica*. We do not have enough evidence at present to know whether *B. eocenica* represents a link to a *Bowenia* ancestor that had pinnules with a midvein that was lost over time or whether it represents an isolated instance of developing a midvein that did not persist through to the present. It is important to note that because *Bowenia* is the only extant cycad with bipinnately compound leaves, the rachis bearing the pinnule is therefore probably equivalent to a pinna midvein (Stevenson

Fig. 6 Line drawings of the venation of pinnules of selected fossil and living cycads. A, Extant *Chigua restrepoi* (modified from Stevenson et al. 1996; Uzunova et al. 2001). Note the midvein that runs for about two-thirds of the length of the pinnule and the high-angle dichotomously branching veins that arise from it and terminate in serrations. B, Fossil *Bowenia eocenica* (AN2293). Note the rudimentary midvein that runs for about one-quarter of the length of the pinnule and the high-angle dichotomously branching veins that arise from it and terminate in serrations. C, Extant *Bowenia serrulata*. Note the lack of any midvein and the dichotomously branching veins that terminate in serrations. D, Fossil *Restrephophyllum chiguoides* (modified from Passalia et al. 2010). Note the well-developed midvein and the high-angle dichotomously branching veins that arise from it and terminate in serrations. Scale bar = 2 cm for A, 1 cm for B–D.

et al. 1996), and hence the comparison of venation patterns of *B. eocenica* with *C. restrepoi* is, in fact, a comparison between a pinnule and a pinna.

Discussion

Three fossil species of *Bowenia* are now recorded: *Bowenia papillosa*, *Bowenia eocenica*, and the newly described *Bowenia johnsonii*, as well as several other specimens that may represent these or different species or perhaps even the genus *Eobowenia*. The locations of fossil *Bowenia* demonstrate that the genus must have been common across at least southeastern Australia and north into Queensland along the eastern Australian coast when Australia was still connected to Antarctica. Given the northward movement of Australia following its separation from Antarctica at about 43 Ma (Cande et al. 2000; Sandiford and Quigley 2009), we can conclude that *Bowenia* once extended at least 35 degrees farther south than its current subtropical to tropical distributions. Extant *Bowenia* plants grow close to the ground, and both the leaves and pinnules do not have a clean abscission point; hence, they are inherently unlikely to provide vegetative material into fossil deposits, so these fossil occurrences suggest that *Bowenia* was probably quite common at all sites and particularly so at Lowana Road and possibly Anglesea.

The pinnules of the fossil *Bowenia* species are distinctive, with two species, *B. eocenica* and *B. papillosa*, having relatively small pinnules with clearly serrate margins, while *B. johnsonii* has larger pinnules with very small rounded serrations. The fossil species as a group has significantly lower stomatal density and size than the living species, indicating that the relative pinnule area allocated to stomata has increased since the Eocene. Hill (1978, 1998b) considered entire-margined pinnules to be the probable ancestral state in *Bowenia*, but a combination of the description of *Eobowenia* and the discovery of more serrate-margined fossil *Bowenia* species and specimens makes this less likely.

The change in the Australian environment since the Eocene has been extreme and varied, and hence an explanation for the change in pinnule morphology and stomatal size and density is not straightforward (see this article). Since the Eocene, the Australian landmass has moved northward, and the photoperiod has altered dramatically, as has the angle of the sun in the sky during the growing period. There is also strong evidence that the Australian Eocene climate was relatively warm, with extremely high humidity throughout the year that dampened temperature extremes. Many of the fossil cuticles at the sites examined have high densities and diversities of epiphyllous fungi, which indicates extremely humid environments with no dry season (Lange 1976, 1978; Wells and Hill 1993). Furthermore, atmospheric CO₂ levels during the Early Eocene were high by modern standards (Pagani et al. 2005; Lowenstein and Demicco 2006; Anagnostou et al. 2016), enhancing the global greenhouse effect as well as providing abundant CO₂ for photosynthesis.

The small pinnules of *B. eocenica* and *B. papillosa* may have been advantageous in a warm climate, as small leaf size results in a thinner boundary layer (Yates et al. 2010), which enhances convective leaf cooling relative to large pinnules with thicker boundary layers. While this is well established for canopy trees,

it is less well understood for understory plants, and Wright et al. (2017) concluded that in modern forests, the lower energy inputs in shaded situations may allow for relatively larger leaf sizes there. Hence the small, moderately serrate pinnules of *B. eocenica* and *B. papillosa* were unexpected, since both species occur among diverse angiosperm floras with relatively large leaf sizes, similar to those of extant tropical or subtropical rain forest. It is possible that the leaves of the fossilized species with small pinnules may have been tripinnate. Johnson (1959) noted that extant *Bowenia* has bipinnate leaves, but Wilson (2004) noted occasional tripinnate leaves in *B. serrulata*, and these leaves had significantly more and smaller pinnules per leaf than bipinnate leaves. There is a possible advantage in having tripinnate leaves for these understory cycads growing in complex rain forests in dense shade, at high latitudes, and where the sun is always low in the sky and coming from different directions near the horizon throughout the day. Small but numerous photosynthetic units may be a very effective way to maximize light uptake in such an environment where sunflecks are the major source of light (this article). Although no extant cycads from high latitudes are tripinnate, fossilized tripinnate cycads and ferns have been described (e.g., Artabe and Stevenson 1999; Carvalho et al. 2013). *Bowenia johnsonii* probably did not follow the same strategy as *B. eocenica* and *B. papillosa*. It has relatively large pinnules compared with the other fossil *Bowenia* species and hence was more likely to have had bipinnate leaves. The larger surface area of these pinnules may represent another strategy to maximize light uptake in the high-latitude, understory environment, a scenario that is consistent with the very low stomatal conductance associated with the small, low-density stomata. Also consistent with this idea is the fact that extant *B. spectabilis*, which grows in rain forest understories, has larger pinnules than *B. serrulata*, which typically occurs in more open environments.

Among the living species of *Bowenia*, serrations appear to increase in presence and size as the vegetation opens. Based on the extant species, and given the likely light environment when the Eocene forests were growing, entire-margined pinnules would have been predicted for the fossil taxa. However, all these taxa are serrate (figs. 2, 4; table 2). Many hypotheses have been proposed to explain the presence of serrate margins in leaves. With genera that have only simple dichotomous venation, it is possible that as photosynthetic area reduces in cooler and/or drier environments, the lamina shrinks back from the margin more quickly than the vein endings, and hence the individual vein endings become serrations. Given that extant *B. spectabilis* can be either entire-margined or minutely serrate, depending on the vegetation type it occurs in, this trait is clearly variable within the genus.

Conclusion

Bowenia is a particularly interesting genus that is far removed morphologically from other extant and fossil cycads, with the exception of *Eobowenia*. The fossil record of *Bowenia* is important in determining the past distribution of the genus, and also provides some insight into the evolution of the extant species, but as yet offers no information on the origins of the genus. It is likely that further Cretaceous finds of *Bowenia* and closely re-

lated taxa will be required to answer more detailed questions about the evolution of this genus.

Acknowledgments

We thank the Queensland Herbarium (BRI), National Herbarium of Victoria (MEL), and Australian Tropical Herbarium (QRS) for providing specimens and the South Australian Her-

barium (AD) and Melbourne Museum for fossil specimen loans. We also thank the Exploration Data Centre of the Geological Survey of Queensland for core samples, Dr. Mike Macphail for opinions on the palynology of key sites, and the Australian Research Council for the funding that made this research possible. We are especially grateful to Professor Sergio Archangelsky and Dr. L.C.A. Martínez for providing images of the holotype of *Eobowenia incrassata*.
