## SUMMARY

Biogeography is the study of the geographic distribution of taxa and their attributes in space and time. There are three main processes that together are considered to pattern the distribution of taxa: dispersal, vicariance and extinction. Over the years, three quite distinct schools have developed within historical biogeography, which all comprehend a number of methodological directions: pattern-based, event-based, and model-based methods.

The Brassicaceae is one of the largest plant families and is considered to comprise around 3660 species distributed over 320 genera. The family was thought to have originated in the New World based on the distribution of either the 'basal' placed tribe Theylopodieae and later the Hesperideae. An Old World origin, based on the genus *Aetheionema* now considered to be sister to all other Brassicaceae, is now proposed. It is assumed that the origin can be found where at the moment the largest diversity in species is, which would be the Iranoturanian region. In this project, this assumption is investigated.

The most recent phylogenetic tree covering the whole family from Couvreur et al. is based on ITS, *chs*, *adh*, *matK*, *trnL-F*, *ndhF*, *rbcL* and *nad4* (Couvreur et al., 2010). This phylogenetic tree is updated with all available data from GenBank and aligned with two settings in the alignment program MAFFT. RAxML Maximum Likelihood, TNT parsimony and Neighbour Network analyses were run.

GBIF distribution data on genus level was used to define areas of endemism which were assigned to all terminals in the phylogenetic tree.

A Bayesian-DIVA analysis based on 200 TNT phylogenetic trees gave the result that a combination of the regions 'Iberian Peninsula & North Western Africa', 'Central Mediterranean & Southern Balkan', 'Western and Central Anatolia & Levantine coast', and 'Caucasus, Eastern Anatolia & Iranian mountain ranges' forms the ancestral range of all Brassicaceae.

Based on the results of the Bayesian-DIVA analysis, the conclusion can be drawn that the Iranoturanian region is indeed part of the area of origin of the Brassicaceae. However, there are some issues with the underlying alignment which make both the phylogenetic inference and the historical biogeographical analysis unreliable.

# 1. INTRODUCTION

## HISTORICAL BIOGEOGRAPHY

Biogeography is the study of the geographic distribution of taxa and their attributes in space and time (Morrone, 2010). Biogeographers track the distribution of a (group of species) throughout history (Ree & Smith, 2008). One of the best known examples is the reconstruction of the radiation of humans over the earth (Harcourt, 2012).

In biogeography, three rather different sciences meet; biology, geology and geography (Cox & Moore, 2010; Morrone, 2010). This makes it a quite varied field, which perhaps is why there are so many different approaches and theories developed in the two centuries of research in this field (Morrone, 2009). Morrone lists an exemplary 23 of these approaches for biogeography in general, but concludes that all are part of one of only two disciplines: ecological and historical biogeography (Morrone, 2009).

Ecological biogeography was started by Linnaeus, who attempted to describe all then known animals and plants and recorded the required environmental conditions. This type of biogeography focuses on the biotic and abiotic interactions of a species on a short time span.

After Darwin introduced the theory of evolution, it was accepted that the distribution of species can change over time according to their ecological requirements (Morrone, 2009). These patterns of distribution of species (or higher taxonomic levels) on much larger timescales is the focus of historical biogeography (Morrone, 2009).

There are three main processes that together are considered to pattern the distribution of taxa: dispersal, vicariance and extinction (Figure 1, Morrone 2010).

In dispersal, a species moves from its current area of distribution to another area, usually over a barrier. In this newly colonised area, it develops into another species. This concept is not to be confused with dispersion, which is the movement of a species within its original area of distribution (Cox & Moore, 2010; Crisci, 2001; Morrone, 2009).

With vicariance the original species does not move over a barrier, but one appears splitting the area of distribution and causing speciation (Cox & Moore, 2010; Morrone, 2009).

In extinction, part of the ancestral population falls away, causing it to be split up. Separated sub-populations can remain, which results in speciation (Crisci, 2001; Morrone, 2009).

FIGURE 1. THE THREE BIOGEOGRAPHICAL PROCESSES: DISPERSAL, VICARIANCE AND EXTINCTION (AFTER MORRONE, 2010).

The analytical approach to biogeography really developed since the acceptance of continental drift in the 1960's. There were quite heated discussions how the above mentioned processes should be implemented in an analytical method and which was the best (Bremer, 1992, 1995; Brooks, 1990; Ronquist, 1994, 1995, 1997; Wiley, 1988). All methods that have been developed are in some way based on the three processes, but differ in how these are treated in the analyses, and in the assumptions concerning patterns and processes of change in geographical distributions.

Over the years, two quite distinct schools of methods have developed within historical biogeography, which both comprehend a number of methodological directions: pattern-based and event-based methods (Ronquist & Sanmartín, 2011). Pattern-based methods 'establish connections between distributional patterns and evolutionary processes after the primary analytical results have been obtained (Ronquist & Sanmartín, 2011). A major field in the pattern-based school is cladistic biogeography. An important part of cladistic biogeography is the constructing of area cladograms based on procedures called Assumption 0, 1, and 2 (Error! Reference source not found.). In this Figure, the assigned areas for the exemplary cladogram on top are explained. Under Assumption 0, when a taxon occurs in more than one area, they are considered to be a monophyletic group. In contrast, under Assumption 1, they can either be mono- or paraphyletic. Last, under Assumption 2, the areas can mono-, para- or polyphyletic (Crisci, Katinas, & Posadas, 2003).

FIGURE 2. AREA CLADOGRAM WITH A WIDESPREAD TAXON IN AREAS 1 AND 2, AND DERIVATION IN RESOLVED AREA CLADOGRAMS UNDER ASSUMPTIONS 0, 1, AND 2 (AFTER CRISCI, KATINAS, & POSADAS, 2003)

One of the best known pattern-based methods is Brooks Parsimony Analysis (BPA, Wiley, 1987). This method is primarily based on Assumption 0 and consists of two analytical steps: primary and secondary BPA. In primary BPA, an area versus cladogram matrix is formed (Figure 3, left). In the cladogram, all terminals and all nodes are given a letter A through G. Then, for each of the areas 1, 2, 3, and 4, the letters (terminals and nodes) are scored they pass when traced back to the base of the cladogram. Area 1, for example, occurs on terminal A and only passes additional node G underway to the root. Area 4 occurs on terminal D and passes nodes E, F, and G, which are thus scored in the matrix. In imaginary outgroup area is defined, for which all terminals and nodes are scored zero (absent). In secondary BPA, areas that may cause problems in the analysis (for example in the case of extinction, which would mean a loss of the area, or duplication, where multiple terminals are present in the same area), are split up and scored over the separate scenario's individually (Figure 3, right).

FIGURE 3. (LEFT) AREA VS CLADOGRAM MATRIX WITH COMPLETE DATA AND NO AMBIGUITY ('OUTGROUP' IS NOT SHOWN). (RIGHT) (AFTER CRISCI ET AL., 2003).

Event-based methods on the other hand are based on a cost matrix where each of the vicariance, dispersal and extinction processes is assigned a certain cost. These three processes are then inferred over a phylogenetic tree. This type of methods is based on parsimony, thus the least costly outcome (the most parsimonious) is the final result (Cox & Moore, 2010; Morrone, 2009; Ronquist & Sanmartín, 2011; Sanmartín, 2006).

One of the best known event-based method is Dispersal-Vicariance Analysis (DIVA), developed by Ronquist (Ronquist, 1997). DIVA came as an answer to cladistic biogeography, to which Brooks parsimony belongs (Bremer, 1992, 1995; Ronquist, 1994, 1997). DIVA 'reconstructs ancestral distributions from one given phylogenetic hypothesis, without assuming a particular process a priori' (Morrone, 2009). Vicariance is favoured over dispersal and extinction, which are subsequently considered to be more costly in the parsimony analysis (Cox & Moore, 2010; Morrone, 2009; Yu, Harris, & He, 2010b).

In recent years, with the coming of model based phylogenetic inference, also model-based historical biogeographic methods (both Bayesian inference and Maximum Likelihood based) have been developed. With these methods, it is now possible to have an statistical based indication for the chance of a particular area occurring on a particular node in the phylogenetic tree.

Examples of model-based methods are S-DIVA and Bayesian DIVA. These are developed in response to some troubles encountered with the original DIVA. DIVA can only handle phylogenetic trees that are completely resolved and it is assumed that the tree topology is known without error. In addition, there is uncertainty with the ancestral area optimisation because the analysis often results in a number of optimal distributions which are similarly parsimonious (Ali, Yu, Pfosser, & Wetschnig, 2012; Nylander, Olsson, Alström, & Sanmartín, 2008).

Therefore, two new programs have been developed that take care of these uncertainties. These are Bayesian-DIVA (Nylander et al. 2008) and Statistical-DIVA (S-DIVA, Yu, Harris, and He 2010a). In Bayesian-DIVA, a number of Bayesian inferences are optimised before a DIVA analysis is run. In S-DIVA, the S-DIVA value, which combines the phylogenetic and geographical uncertainties, gives statistical support to the result of the analysis (Yu et al., 2010b). Also, for each node the frequency an ancestral range occurs over all reconstructions are averaged (Ojeda, Novillo, Ojeda, & Roig-Juñent, 2013).

## BRASSICACEAE

The Brassicaceae is one of the largest plant families and is considered to comprise around 3660 species distributed over 320 genera (Al-Shehbaz, 2012; Koch, Karl, German, & Al-Shehbaz, 2012). It is also an important plant family containing crop species, weeds and model organisms (Beilstein, Nagalingum, Clements, Manchester, & Mathews, 2010; Couvreur et al., 2010; Koch & Marhold, 2012) which makes it interesting to research the origin of the family.

From as early as the beginning of the 20<sup>th</sup> century, the origin of the Brassicaceae has been inferred. In the first theory from these early days, the family was thought to have originated in the New World based on the distribution of either the basal placement of the tribe Theylopodieae and later the Hesperideae. With the coming of molecular studies this view shifted and an Old World origin, based on the genus *Aetheionema* now considered to be sister to all other Brassicaceae, is proposed (Al-Shehbaz, Beilstein, & Kellogg, 2006; Franzke, Lysak, Al-Shehbaz, Koch, & Mummenhoff, 2011; Hauser & Crovello, 1982; Koch, Al-Shehbaz, & Mummenhoff, 2003).

In recent years the phylogeny of the Brassicaceae has thoroughly been revised with the help of DNA-based research (Bailey et al., 2006; Beilstein et al., 2010; Couvreur et al., 2010; Warwick, Mummenhoff, Sauder, Koch, & Al-Shehbaz, 2010). The most recent phylogenetic tree covering the whole family is from Couvreur et al. (2010). This inference is based on ITS, *chs*, *adh*, *matK*, *trnL-F*, *ndhF*, *rbcl* and *nad4*. All genomes (nuclear, chloroplast and mitochondrial) are thus covered. Currently, phylogenetic trees are inferred not for the family as a whole but on the tribal level (Jordon-Thaden, Al-Shehbaz, & Koch, 2013; Karl & Koch, 2013). This approach is chosen because the relationships on this level are not yet adequately resolved causing a considerable amount of phylogenetic uncertainty resulting in a lowly supported backbone (Koch, 2013).

At the moment, a number of overarching lineages is recognised within the Brassicaceae (Couvreur et al., 2010; Koch & German, 2013). These major lineages (Lineage I, Lineage II, Extended Lineage II, and Lineage III) each consists of a number of tribes and together are considered to compose the structure for the entire family (Franzke et al., 2011).

Unfortunately, as researchers agree, the Brassicaceae fossil record is rather poor (Franzke, German, Al-Shehbaz, & Mummenhoff, 2009; Franzke et al., 2011). There are fossilised pollen from the early Middle Miocene, Upper Miocene and Latest Cretaceous available, though the last one is doubtful. Also, there is a fossil fruit from the Oligocene, but it remains unclear whether it actually belongs to the family (Franzke et al., 2011).

A lot of historical biogeographical research is being done in recent years. In almost every phylogenetic study, the ancestral areas are inferred alongside the ages of clades.

In this thesis, we chose to perform a historical biogeographical analysis on the entire Brassicaceae because Schranz et al. (2012) proposed the hypothesis that the origin of a family as vastly radiated as the Brassicaceae can be found there were at the moment the largest diversity is (Schranz et al. 2012). In case of the Brassicaceae that would coincide with the area of diversity of the genus *Aethionema* (Schranz, Mohammadin, & Edger, 2012).

Based on the previous, the following question with associated hypothesis is posed:

Where lies the centre of origin of the Brassicaceae?

- The origin can be found were at the moment the largest diversity in species is – Iranoturanian region (Al-Shehbaz et al., 2006)

## 2. MATERIAL AND METHODS

In this chapter, I give an overview of the methods I used to carry out a historical biogeographical analysis. First, I will explain how I performed the phylogenetic inference, next how I came to the geographical distribution, and last a description of the biogeographical analysis itself. Since this is a MSc thesis project with a lot of trial and error, not all methods I tried were used in the final analysis. These steps are clustered under the heading 'Additional Methods'.

### 2.1 PHYLOGENETIC ANALYSIS

First, the sequence data of Couvreur et al. (2010) was requested for the phylogenetic inference. This data set was chosen as a starting point because it is the most recent and most complete genus level study to this point. This study includes the nuclear genes ITS, *chs* and *adh*, the chloroplast genes *ndhF*, *rbcL*, *matK*, the *trnL* intron and *trnLF* spacer and the mitochondrial gene *nad4*. The alignment from Couvreur et al. (2010) was kindly provided by Dr. Couvreur.

To make the taxonomic coverage of this Brassicaceae dataset at the genus level as complete as possible, relevant sequences were sought in GenBank. This included sequences of the above named genes from genera that had not yet been developed, as well as sequences of new genera. In addition, sequences from relevant outgroups from the Cleomaceae, Capparidaceae and genera from other families within the Brassicales were added.

The gathered sequence data are thus species-level data, and it is here assumed that the separate sequences for each species over the eight genes are of one and the same individual. These separate sequences are thus combined to form one concatenated sequence for that one species.

No additional sequences were generated since it is not the intention of this project to update the most recent phylogenetic tree of Couvreur et al. (2010). It is merely used as a starting point for this project.

The sequence data for each gene was gathered in Mesquite (Maddison & Maddison, 2010) and Geneious (Drummond et al., 2011) was used to put these in a rough phylogenetic order with the help of Robin van Velzen. This was done by loading the gene alignments in Geneious, letting it form a 'quick and dirty' phylogenetic tree, and having it order the alignment to match that order. These gene-sets were then aligned using the auto and G-INS-i settings of MAFFT online (<http://mafft.cbrc.jp/alignment/software/>), giving a total of 16 gene alignments. I refrained from manual adjustments because I wanted to keep the alignment objective and not subjected to subjective interpretation.

Then, the separate alignments were assembled with SequenceMatrix (Vaidya, 2011) into a matrix for these two MAFFT options separately.

Also, because the taxonomic sampling (number of taxa per gene-set) differs quite substantially (from 6% for *adh* to 82% for ITS, Appendix B), additional phylogenetic analyses including only those genes with a completeness of more than 30% was carried out. These are *nad4*, ITS, *ndhF* and *trnLF*. Table 1 gives an overview of all the matrices formed by the alignment – covering options.

TABLE 1. OVERVIEW OF MATRICES, THE GENES THESE CONSIST OF, AND THE ALIGNMENT METHOD USED.

	Genes	Alignment Method MAFFT
<b>MAFFT_4</b>	ITS, <i>ndhF</i> , <i>trnLF</i> and <i>nad4</i>	Auto
<b>MAFFT_4_slow</b>	ITS, <i>ndhF</i> , <i>trnLF</i> and <i>nad4</i>	Auto
<b>MAFFT_8</b>	ITS, <i>chs</i> and <i>adh</i> , <i>ndhF</i> , <i>rbcL</i> , <i>matK</i> , <i>trnLF</i> and <i>nad4</i>	G-INS-i
<b>MAFFT_8_slow</b>	ITS, <i>chs</i> and <i>adh</i> , <i>ndhF</i> , <i>rbcL</i> , <i>matK</i> , <i>trnLF</i> and <i>nad4</i>	G-INS-i

A number of applications in the phylogenetic inference program TNT (Goloboff et al. 2008) was used on these four matrices. For these analyses, the matrices were exported to TNT format from Mesquite.

A preliminary Traditional Search (500 replications) was run to get insight in the tree topology resulting from the matrix. Then, an analysis with the Sectorial and Ratchet settings combined, using the default settings (200 replications), was run. In a Sectorial tree search, a subset of the data is created based on large clades from a phylogenetic inference. These clades (or subsets) are then optimised and recombined (Goloboff, 1999). With Ratchet, a number of characters from an initial phylogenetic tree is selected and their weight (representing the influence) is altered (Nixon, 1999).

The resulting phylogenetic trees were made suitable for further use by importing them in Mesquite alongside their original matrix and exporting them as a Nexus tree file.

RAxML-HPC2 on XCEDE through the Cypres Science Gateway (Miller, Pfeiffer, & Schwartz, 2010; Stamatakis, 2006) was used for Maximum Likelihood analysis for all separate genes and the four matrixes mentioned above. For this analysis, the matrices were exported to Phyllip format from Mesquite.

SplitsTree4 (Huson & Bryant, 2005) was used to check the ambiguity of the phylogenetic information within the matrices. I did a 'quick and dirty' analysis with the default Uncorrected P-value settings and an analysis with the GTR+Gamma model. In this analysis, the Base Frequencies were set to Empirical frequencies, meaning frequencies of the bases as actually found in the data. The Site Rate Variation was set to Gamma, with an alpha parameter of 0.5 and proportion invariable sites on 0.5.

#### ADDITIONAL METHODS

I am aware that the MAFFT tool used for alignment of the matrixes does not take the phylogenetic information into account and that this can cause biases in the subsequent analyses (Anisimova, Cannarozzi, & Liberles, 2010; Löytynoja & Goldman, 2008). An example of an aligning program that does use the phylogenetic history is PRANK (Löytynoja & Goldman, 2005). PRANK was used as one of the programs for aligning of the data, but unfortunately the resulting matrix was so pulled apart that no coherence between the characters was left. I therefore decided not to continue with these matrices in the further analysis.

It is desirable to check how 'well' the matrices have been aligned after using an aligning tool as MAFFT or PRANK. Since I wanted to refrain from any subjective interpretation of the data, I used the program GBlocks (Talavera and Castersana 2007). GBlocks finds the poorly aligned positions in the matrix and indicates where they should be omitted (Castresana, 2000). However, I decided not to use this method because too many areas (that looked adequate when checked by eye) were indicated as weak and would have to be removed from the alignment.

A lot of phylogenetic information can be derived from indels, but how to handle them is subject to an extensive debate (Simmons, Müller, & Norton, 2007; Simmons & Ochoterena, 2000). One can either identify and/or interpret indels by eye, or use one of the available programs. Since I wanted to keep the matrix as objective as possible (as with the manual aligning), I chose to use the program SeqState for this analysis (Müller, 2005). Unfortunately it turned out that SeqState over-interpreted the information in the matrixes and assigned substantially more indel characters than could be justified when checked by eye. Therefore I decided not to continue with these analyses and thus did not take into account possible indel information.

In addition to the TNT and RAxML analysis, I used Bayesian methods to infer phylogenetic trees. I used both MrBayes 3.2.1 on XSEDE (Ronquist et al., 2012) and a local version of MrBayes for all above named datasets as well as all sixteen separate gene alignments. Unfortunately, due to time constraints it turned out not to be feasible to successfully carry out these analyses. In Appendix B. Exemplary script used in MrBayes an exemplary script designed for these analyses is provided.

## 2.2 GEOGRAPHICAL DISTRIBUTION

For the historical biogeographical analysis, it is important to establish the geographic distribution of the terminals in the phylogenetic tree as comprehensive as possible. Instead of using a species level distribution (since the matrices consist of species level sequence data), the geographic dispersal information of the Brassicaceae on genus level was gathered. A further explanation for this decision is provided in the 'Geographical Distribution' section of the Discussion and Conclusion chapter.

To do this, the Global Biodiversity Information Facility (GBIF, The Global Biodiversity Information Facility, 2013) was primarily used. On this website, amongst other things, specimen data from all online published databases from herbaria is collected. The distribution data of all relevant genera (those that are represented in the phylogenetic tree) was downloaded and checked the data in Google Earth (Google, 2014). Suspicious outliers were traced and removed from the dataset when necessary. As can be seen in Appendix A (column 'Percentage'), the percentage of records in GBIF that is geographanced per genus was checked. When this percentage was lower than 20, place marks to unappointed places were manually added in Google Earth based on the data available in GBIF.

With these distribution maps per genus, relevant geographic areas were formed to accurately cover the total distribution of the entire phylogenetic tree. Hereby the example of Karl & Koch was followed, who did the same in their Ancestral Area Reconstruction of the tribe *Arabideae* (Karl & Koch, 2013).

Karl and Koch based their distribution on the global ecoregion map developed by Olson et al. (Figure 4; Olson et al., 2001). Based on geographic distribution data of a large set of plant and animal species, Olson et al. developed a total of 867 ecoregions. They intended for these ecoregions to be used as a 'framework for comparisons among units and the identification of representative habitats and species assemblages' (Olson et al., 2001). The ecoregions thus represent the natural borders of the species habitats, instead of political boundaries (Kier et al., 2005) and are widely used in conservation studies (Hoekstra, Boucher, Ricketts, & Roberts, 2004; Olson et al., 2001).

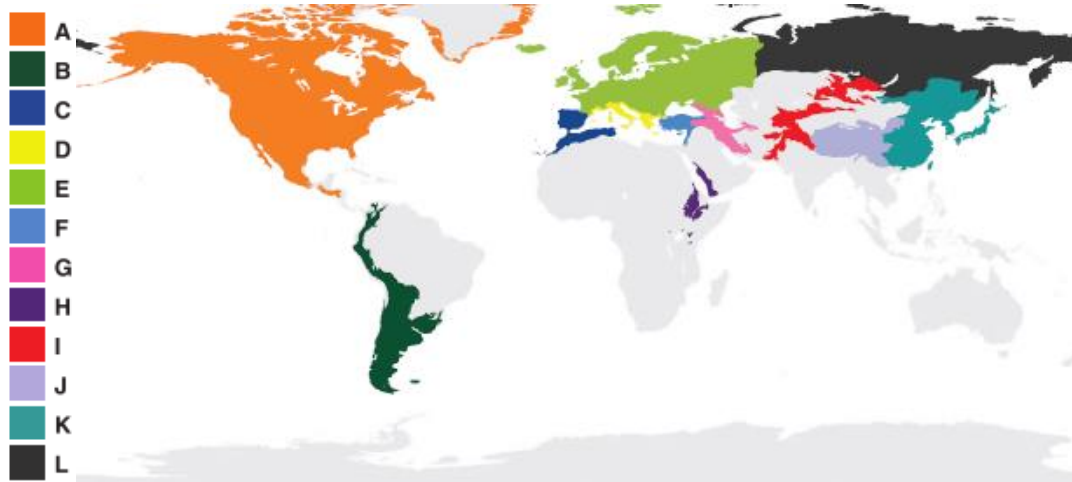

FIGURE 4. THE 867 ECOREGIONS OF OLSON ET AL. (2001).

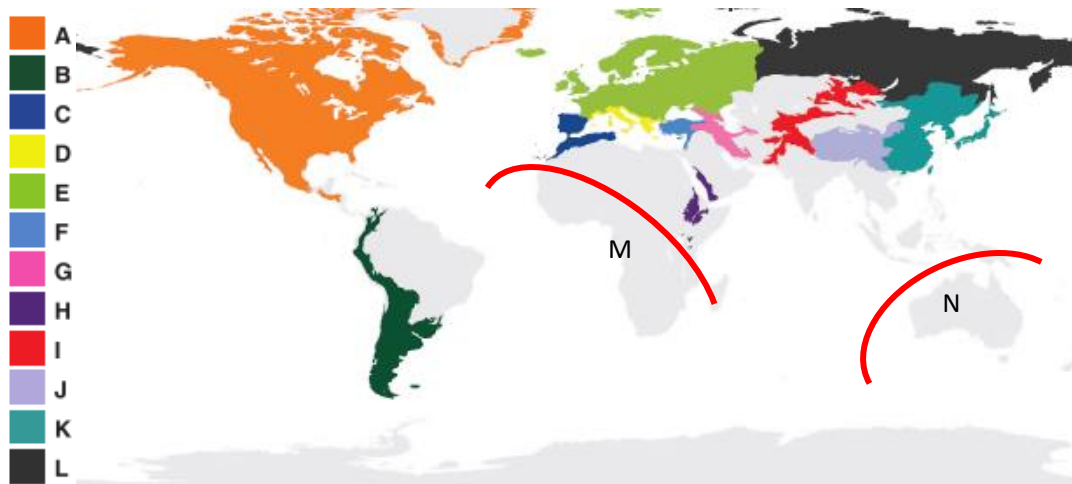

Using these ecoregions, the areas as proposed by Karl and Koch (Figure 5) and based on overlapping distributions in the data of the genera gathered in Google Earth, a total of 14 geographical areas was designed (Figure 6). These include all areas as designed by Karl and Koch, and now include Sub-Saharan Africa and the Australia/New Zealand combination as well.

Then, each genus was assigned to at least one of these geographical areas. In the case of a widespread genus as for example *Alyssum* L. it was necessary to include a number of areas to ensure the entire distribution was taken into account.

For each of the four matrices, the appropriate areas were assigned to all taxa in Excel. These data were then transported to four separate .CSV files; one for each matrix, making it suitable for use in RASP.

**FIGURE 5. GEOGRAPHICAL AREAS USED BY KARL & KOCH (2013).** A: NORTH & CENTRAL AMERICA, B: SOUTH AMERICA, C: IBERIAN PENINSULA & NW AFRICA, D: CENTRAL MEDITERRANEAN & SOUTHERN BALKANS, E: EUROPE, F: WESTERN AND CENTRAL ANATOLIA & EASTERN MEDITERRANEAN, G: CAUCASUS, EASTERN ANATOLIA & IRANIAN MOUNTAIN RANGES, H: HIGH MOUNTAINS OF THE ARABIAN PENINSULA AND EASTERN AFRICA, I: CENTRAL ASIAN MOUNTAIN RANGES, J: EASTERN HIMALYA AND TIBET-CHINEASE MOUNTAINS, K: EASTERN ASIA, L: SIBERIA & RUSSIAN FAR EAST.

**FIGURE 6. PROPOSED GEOGRAPHICAL AREAS (AFTER KARL & KOCH 2013).** A: NORTH & CENTRAL AMERICA, B: SOUTH AMERICA, C: IBERIAN PENINSULA & NW AFRICA, D: CENTRAL MEDITERRANEAN & SOUTHERN BALKANS, E: EUROPE, F: WESTERN AND CENTRAL ANATOLIA & EASTERN MEDITERRANEAN, G: CAUCASUS, EASTERN ANATOLIA & IRANIAN MOUNTAIN RANGES, H: HIGH MOUNTAINS OF THE ARABIAN PENINSULA AND EASTERN AFRICA, I: CENTRAL ASIAN MOUNTAIN RANGES, J: EASTERN HIMALYA AND TIBET-CHINEASE MOUNTAINS, K: EASTERN ASIA, L: SIBERIA & RUSSIAN FAR EAST, M: SOUTHERN AFRICA, N: AUSTRALIA AND NEW ZEALAND.

## 2.3 BIOGEOGRAPHICAL ANALYSES

For each of the four matrixes described above, a historical biogeographical analysis using the Bayesian Binary Method (BBM) implementation in RASP (Nylander et al., 2008; Yu, Harris, & He, 2012) was carried out.

In RASP, a number of background phylogenetic trees has to be provided to form a phylogenetic range. For this, 100 parsimonious TNT phylogenetic trees obtained in the Traditional search were used. Then, a 'Condensed Tree' has to be provided, for which the most parsimonious TNT phylogenetic tree obtained with the Sectorial and Ratchet setting as described above was used. This is the starting tree on which the phylogenetic uncertainty from the background trees is projected. Hereafter, a distribution file is imported wherein the area ranges of all terminals are defined.

In the BMM menu, a number of settings can be chosen by the operator. For example; all settings of a traditional Bayesian MCMC, the root distribution and maximum number of areas per node. Table 2 gives an overview of all combinations of settings used in BBM for each matrix.

From the literature it is known that widespread species can be a possible source of bias in a biogeographic analysis (Karl & Koch, 2013; Morrone & Crisci, 1995). I therefore pruned the results of the TNT analysis and excluded those taxa that were assigned more than six areas. These matrices are named: MAFFT\_4\_pruned, MAFFT\_8\_pruned, and MAFFT\_8\_slow\_pruned. This thus gives a total of seven matrices analysed with BBM.

TABLE 2. OVERVIEW OF COMBINATION OF SETTINGS IN RASP.

Number of generations	Chains	Temperature	Root distribution	Number of areas
100.000	4	0.1	Outgroup	4
			Outgroup	6
			Null	4
			Null	6
			Wide	4
			Wide	6

## 3. RESULTS

### 3.1 PHYLOGENETIC ANALYSIS

#### RAXML BOOTSTRAP

In Appendix C.1 through C.4 the results of the RAXML Bootstrap analysis are displayed. While the backbone of all phylogenetic inferences forms a major polytomy and the overall bootstrap support is low, Lineage I (red), Lineage II (purple), Extended Lineage II (green) and Lineage III (blue) can be observed in all four phylogenetic trees. Table 3 gives an overview of the support values of these lineages per matrix. Within these lineages, most clades are fairly well resolved and are fairly well supported. However, the higher we go in the phylogenetic tree, the lower the support becomes. The clades forming Lineage II essentially are part of one major polytomy.

A number of taxa are now retrieved in a different lineage than was the case in Couvreur et al. (2010). These are: *Biscutella didyma*, *Lunaria rediviva*, *Magadenia pygmaea*, *Orychophragmus violaceus*, *Fourraea alpina*, *Hornungia petraea*, *Arabis drummondii*, *A. fendleri*, *A. lyalli*, *A. parishii*, *A. lignifera*, *Lunaria annua* (partial), and *Conringia planisiliqua*. Table 4 gives an overview of these taxa per matrix, the lineage they were placed according to Couvreur et al. (2010), the lineage they are placed in the RAXML Bootstrap analysis, and their bootstrap support.

#### TNT

Appendix C.6 through C.9 show the results of the TNT parsimony analysis for all four matrices. As can be seen from the figures, the major lineages are relatively well retrieved. Only Extended Lineage II (green) is no longer monophyletic except for the MAFFT\_8\_slow matrix.

Again, a number of taxa have crossed lineage borders and are retrieved in a different lineage as is the case with the RAXML Bootstrap analysis. These are: *Orychophragmus violaceus*, *Biscutella didyma*, *Lunaria rediviva*, *Magadenia pygmaea*, *Fourraea alpina*, *Enarthrocarpus clavatus*, *Isatis brevipes*, *Dontostemon dentatus*, *Dontostemon glandulosus*, *Hornungia petraea*, *Arabis glabra*, *A. lyalii*, *A. parishii*, *A. drummondii*, *A. fendleri*, *A. lignifera*, *A. pauciflora*, *Zuvanda crenulata*, *Conringia planisiliqua*, *Iberis procumbens*, and *Sameraria armena*. Table 4 gives an overview of these taxa per matrix, the lineage they were placed according to Couvreur et al. (2010) and the lineage they are placed in the TNT parsimony analysis.

#### NEIGHBOUR NETWORK

Appendix C.10 through C. 13 show the results of the Neighbour Network analysis performed in SplitsTree under the GTR+ $\Gamma$  model. As can be seen from the figures, the alignments resulted in rather complicated networks. In all cases, a large polytomy is found on one side of the network. On the other side, more network-like behaviour can be seen. The results of the MAFFT\_4 and MAFFT\_8, and the MAFFT\_4\_slow and MAFFT\_8\_slow matrices are quite comparable with each other.

Unfortunately, it was not possible to give Lineage colour indications for these results. Therefore, nothing can be said about these Lineages in this analysis.

<b>J</b>	Eastern Himalaya and Tibet-Chinese mountains
<b>K</b>	Eastern Asia
<b>L</b>	Siberia & Russian Far East
<b>M</b>	Southern Africa
<b>N</b>	Australia and New Zealand

### 3.3 BIOGEOGRAPHICAL ANALYSIS

Because of the large amount of analysis performed in this part of the project, it is not possible to show all the results. The following table (Table 6) gives an overview of the resulting ancestral area for each of the matrices over all types of analyses. Because of time constraints it was not possible to perform a Bayesian DIVA analysis for all matrix-analysis combination.

As can be seen in the table, quite often a \* (indicating RASP was not able to determine the ancestral area) is part of the outcome. When possible, the most likely alternative area has additionally been indicated. Next, the combination of areas 'Iberian Peninsula & North Western Africa', 'Central Mediterranean & Southern Balkan', 'Western and Central Anatolia & Levantine coast', and 'Caucasus, Eastern Anatolia & Iranian mountain ranges' (regions C, D, F, and G) is quite often the resulting ancestral area.

Notable is that the ancestral range often consists of a grouping quite a large number of areas.

**TABLE 6. OVERVIEW OF ANCESTRAL AREAS PER MATRIX AND LINEAGE.** OVERALL IS ANCESTRAL NODE INCLUDING OUTGROUPS; AETHIONEMA IS ANCESTRAL NODE OF ALL BRASSICACEAE; CORE IS ANCESTRAL NODE OF CORE BRASSICACEAE. \* NO OUTCOME; -: NOT POSSIBLE TO DETERMINE; LETTERS: PROPOSED AREAS.

## 4. DISCUSSION AND CONCLUSION

### 4.1 PHYLOGENETIC ANALYSIS

As indicated in the Results chapter, the bootstrap support values for the four Lineages in all four phylogenetic trees are remarkably low. The support values for (almost all) the other nodes are similarly low. This is quite a problem, since the bootstrap support values is a direct reflection of the quality of the underlying alignment. An explanation has thus to be sought there. When looking at the alignment, what strikes is that it is incredibly gappy, in the sense of missing sequences. It appears that one of the reasons for these empty areas have resulted from the large number of species. Because I decided to add all the data available in GenBank, sometimes only one out of a possible eight markers is sampled for a terminal. Also, often a number of species is added per genus which then all comprise one or two markers. This results in a rather pulled apart alignment with not a lot of overlap in species and genera between the separate gene regions. Second, as indicated in the Materials and Methods chapter, there are large differences in taxon sampling completeness. To bypass this problem, I made a separate alignment consisting of only markers with a taxonomic sampling of more than 30%. When we compare the Lineage bootstrap support of the RAxML analysis for MAFFT\_8 to MAFFT\_4, it can be seen that the MAFFT\_4 phylogenetic tree overall does seem better supported. However, the support remains low. In hindsight, it would have been better to eliminate ITS from the matrix along with *adh* and *chl*. These three markers have the highest (ITS, 82%) and lowest (*adh* and *chl*, 6 and 8%) taxonomic sampling. The others have a sampling ranging from 26 through 40%, which are in the same range. It would thus have been better to combine these five genes, because then the alignment would have been far less gappy.

The fact that so many genera seem to be non-monophyletic (i.e. either poly- or paraphyletic) while they 'should' be (Al-Shehbaz, 2012), could be an artefact of the large dissimilarities in gene sampling for each of the species within the genus. It could be that terminals with a similar gene-sampling group together, forcing terminals belonging to the same genus apart. This could be checked by investigating the influence of each of the genes by forming a Phylogenetic Super Network. In such a network (for example formed in SplitsTree) separate gene trees are combined in a network form. It will then be known which taxon corresponds to which line in the network, and the underlying effect of the (lack of) genes can be traced.

What is also of interest for the suitability for phylogenetic analysis of a matrix is how well it is aligned. Usually an alignment tool (i.e. MAFFT and PRANK) is used for alignment, which is then checked by eye. At that point, manual adjustments can be made. I decided not to do this last step because I wanted to compare a number of alignment tools, with which manual adjustment would interfere. As explained in the Materials and Methods section, I used two settings in MAFFT and the program PRANK for this comparison. Unfortunately, as explained above, PRANK resulted in such pulled apart alignments that they were no longer usable for further analysis. The default settings of MAFFT have resulted in a slightly better overall bootstrap node support than the G-INS-i settings of MAFFT. This second setting gives a more thorough analysis and is thus expected to give a better resolved matrix. At first sight it is thus surprising that this setting has resulted in phylogenetic trees with lower bootstrap support. However, if we take in mind that the matrix was already quite gappy and the G-INS-i settings have pulled it apart even further, this result is well explainable.

Since both these alignment settings have resulted in badly aligned regions, which in turn affect the phylogenetic inference, I think it would have been better to choose one alignment tool and afterwards optimise the alignment by hand. This is quite common practise in phylogenetics. Indeed, the alignment

will not be completely objective, but as an operator we can take the decision to make a certain change or leave it as specified by MAFFT.

Another cause for problems with this alignment (and resulting in low bootstrap support values) are the indels. As described above, there are a lot of ways to handle them and I made the choice not to include any indel information. Couvreur et al (2010) did include indel information in their analysis, and it seems that this additional step has helped quite a lot in improving the overall support of the phylogenetic tree. Defining indel positions adds a lot of structure to the alignment, which makes it more easy for a phylogenetic analysis to be performed. Since the program now used to define the indel positions did not give sufficient outcome, the alternative would be to define these by hand. In this project, it was however not possible to carry this out.

The support of the phylogenetic trees is thus quite poor and no conclusions can be drawn from these results. These trees are also not suitable for a historical biogeographic analysis. What we can do is compare the four phylogenetic trees with each other and look at their topology.

At first sight there are no large incongruencies between the RAxML Bootstrap phylogenetic trees. All four major lineages are retrieved in each of these phylogenetic inferences. Within these lineages however, there are some differences. The first thing that stands out is the branching order of the lineages. According to Couvreur et al. (2010) and Franzke et al. (2011) the order is: Lineage I (red), Lineage III (blue), Extended Lineage II (green), Lineage II (purple). However, this does not seem to be the case for matrix MAFFT\_8 and MAFFT\_8\_slow. Here the order of lineages is: Lineage III (blue), Lineage 1 (red), Extended Lineage II (green), Lineage II (purple). However, when we zoom in on the node supporting the split between the clades forming Lineage I, III, and (Extended) Lineage II, we see that the support bootstrap is of no significance. These three clades thus form a major polytomy and nothing can be said about their order.

To check the topology of the rest of the phylogenetic tree, I coloured the remaining terminals in colours corresponding to their supposed Lineage based on the tribal composition of Al-Shehbaz (Al-Shehbaz, 2012). As can be seen from the figure in Appendix C.5, almost all newly coloured terminals are found in their corresponding lineage. As a result, almost all clades are now fully coloured.

One of the reasons quite a number of clades is now fully coloured is synonymy. For example, the genus *Desideria* has become a synonym for the genus *Solms-Laubachia*. In one case it turned out that three genera splitting up a clade were made synonymous to the fourth genus in that clade (*Stubendorffia* = *Winklera* = *Cyphocardium* = *Lithodraba*).

In general, the tree topologies is thus quite acceptable, but there are some causes for concern. One of these is the clade of Outgroup taxa (*Moringa ovalifolia*, *Carica papaya*, *Reseda lutea*) separated from the rest of the Outgroup by the *Aethionemeae*, forcing them just inside the Ingroup. The bootstrap support for this small Outgroup clade in itself is rather low, but the support for the *Aethionema* clade is quite acceptable. A possible explanation for this problem is given in the 'General Comments' section of this chapter. Another troubling terminal is the *Eutrema\_himalaicum* right inside the Outgroup while it is supposed to group inside Extended Lineage II.

The results of the Neighbour Network analysis in SplitsTree correspond to the results of the RAxML analysis. As indicated in the 'Neighbour Network' section of the Results chapter, all four matrices display quite a large polytomy on one side of the network. This part corresponds with the large polytomy that is formed by Lineage II and Extended Lineage II in the RAxML phylogenetic trees. Since it was not possible to colour terminals and nodes in the Networks according to their Lineage placement, no further comparisons can be made.

Because the results of the RAxML Maximum Likelihood analysis are not suitable for a historical biogeographical analysis, I intended to use the results of a Bayesian Inference instead. Unfortunately, as explained in the 'Additional Methods' section of the Materials and Methods chapter, it was not possible to complete these analyses. It seems that MrBayes, used for the Bayesian Inference, had quite a lot of trouble with the amount of missing data. MrBayes uses a lot of parameters, and these have to be 'fed' with information in the form of characters. When there are a lot of gaps, these parameters cannot function optimally and the analysis will be terminated. I therefore run the TNT analyses, as an alternative for the Bayesian Inference.

The results of the TNT parsimony analysis are quite similar to those of the RAxML Bootstrap although a larger number of terminals were not found in the 'right' Lineage. This could be a result of the limited number of replications for the Sectorial - Ratchet combined analysis. As specified in the Materials and Methods chapter, I let this analysis run for 200 replications because in an initial test-run the analysis seemed to reach a platform: it took too much time for the analysis to find shorter trees under these model settings. Since the phylogenetic tree obtained was considerably shorter than those retrieved under the Traditional search, I decided 200 replications were sufficient. However, it can be more parsimonious trees could have been found when the analysis had run for a longer period of time.

The results of the TNT parsimony analysis are thus also not optimal for the historical biogeographical analysis. However, I decided to continue with the analysis using the results of the TNT analysis to get a feel for the data, the type of analysis and the results.

All in all, the combination of normal MAFFT settings and including only the four best sampled genes results in a better tree topology, as well as better lineage bootstrap support. Even though this support is still unacceptably low, I feel this matrix shows the most potential.

## 4.2 GEOGRAPHICAL DISTRIBUTION

For the historical biogeographical analysis, it is important to establish the geographic distribution of all terminals in the phylogenetic tree. In the phylogenetic trees I have inferred in this project, the terminals of the trees represent species. Species level distribution data and corresponding ranges would thus be logical. However, the largest matrices (MAFFT\_8 and MAFFT\_8\_slow) comprise around 570 taxa while the Brassicaceae are considered to comprise around 3660 species (Al-Shehbaz, 2012; Koch et al., 2012). Species level data would thus not give an accurate representation of the true distribution of the Brassicaceae. On the other hand, I do have almost half of all available genera covered in the matrices (391 out of a possible 865 genera). I therefore decided it would be better feasible to use the genus-level distribution data. The effects these distributions might have on the biogeographical analysis are discussed in the 'General Comments' section of this chapter.

To limit subjectivity in assigning areas to the taxa, I took a number of precautions. First, I only used accessions from GBIF with reliable coordinate data as indicated in the 'Geographical Distribution' section of the Material and Methods (exceptions being those genera where no data was available at all). When no specific coordinate data was available, I only used those records with reliable data for, for example, a city or province. In some cases, next to specimens also records specified as 'Human Observation' or 'Living Specimen' were available. I decided not to use these records, because I find a human observation of over 50 years ago without a corresponding specimen unreliable. Also, a living specimen is often part of a botanical garden or collection. In that case, the coordinates of the growing location would be given, and it is questionable whether this location is part of the actual distribution area. For the same reason I

refrained from getting the distribution data from flora. An additional reason for this is that often a quite general distribution area is provided.

In some cases it was not possible to apply this method. Since I intended to base this part of the project solely on data available in GBIF (The Global Biodiversity Information Facility, 2013), I had a problem in the case there were no (acceptable) records available for a genus. In those incidents, I did use information available in flora and other publications.

Even with the above named precautions, I still feel that the assigning of areas could be done more objectively. Forming global areas and letting the operator interpret whether a location falls exactly inside or just on the other side of the boarder is still quite subjective. It would be better to describe the proposed areas by a range of coordinates. For a taxon it can then be determined whether it falls within a particular area based on coordinate data.

### 4.3 BIOGEOGRAPHICAL ANALYSIS

As described above, the MAFFT\_4 matrix shows the most potential and is thus considered to be the 'winning' alignment. Table 6 shows that the most likely ancestral region of all Brassicaceae (including *Aethionema*) is a combination of the regions 'Iberian Peninsula & North Western Africa', 'Central Mediterranean & Southern Balkan', 'Western and Central Anatolia & Levantine coast', and 'Caucasus, Eastern Anatolia & Iranian mountain ranges' (regions C, D, F, and G). The Iranoturanian region is indeed part of this region, making the hypothesis that the Brassicaceae originated in the Iranoturanian region highly plausible.

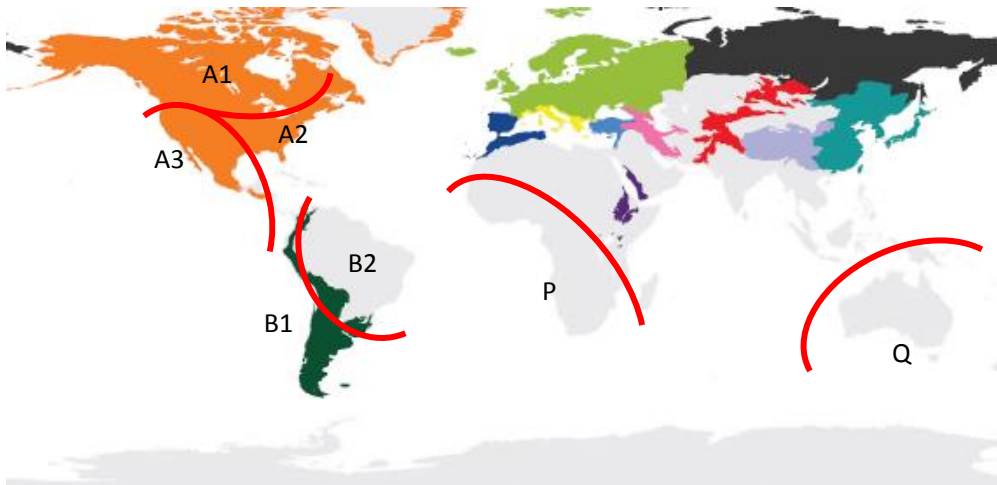

If the origin of the family indeed can be found there, it is to be expected that the ancestral region of all Brassicaceae excluding *Aethionema* can also be found around the same area. As can be seen in the same table, this is indeed the case. Here, a combination of the areas 'Caucasus, Eastern Anatolia & Iranian mountain ranges' and 'Central Asian mountain ranges' is in almost all cases the ancestral region. This region corresponds to an area near to the Iranoturanian region. However, in all these cases the area Northern America - North (area A) is almost as likely to be an alternative ancestral area. This outcome is easily explainable, since two of the latest branches joining the rest of the core Brassiceae are *Idahoa scapigera*, and *Iberisprocumbens*, which occur solely in that region. This placement in the RASP tree topology is not in agreement with that in the RAxML Bootstrap phylogenetic tree. There, these taxa clusters within Extended Lineage II, where it belongs according to the tribal division by Al-Shehbaz (Al-Shehbaz, 2012). The outcomes of the ancestral area analysis are clearly heavily influenced by the incorrect placement of these taxa.

In conclusion; based on the outcome of the BBM analysis, the hypothesis that the area of origin of the Brassicaceae is the Iranoturanian region seems accepted. However, I feel there are so many issues with the underlying alignment, that both the phylogenetic inference and subsequently also the historical biogeographical analysis cannot fully be trusted. We are on the right track, but the results obtained in this project are not enough to confidently accept the hypothesis.

Unfortunately, I encountered a number of problems with RASP. Based on the ecoregions developed by Olson et al. (Olson et al., 2001), I had formed the following areas (Figure 7). However, it is not possible in RASP to assign that many areas; the maximum number is fifteen (ranging from A through O; Yu, Harris, & He, 2010a; Yu et al., 2012). Since I find this maximum number rather arbitrary, I contacted the authors of the programme with the question whether this number could be increased. Unfortunately, I did not receive any response. I therefore followed the advice of Pulcherie Bissiengou and grouped the three

North American areas together. This is permitted, because you should also take geographic history into account when forming these areas. For the same reason, it is common practice to group Madagascar together with (Southern) Africa and New Zealand together with Australia. Because of their shared history, we can group them together even though the areas in itself may differ substantially.

**FIGURE 7. ORIGINAL AREA DIVISION (AFTER KARL & KOCH, 2013).** A1: NORTHERN AMERICA – NORTH; A2: NORTHERN AMERICA – MIDDLE/EAST; A3: NORTHERN AMERICA - SOUTH/MIDDLE AMERICA; B1: SOUTH AMERICA – WEST; B2: SOUTH AMERICA – EAST; P: SOUTHERN AFRICA; Q: AUSTRALIA AND NEW ZEALAND.

Then, I had planned on using both the S-Diva as well as the Bayesian implementation of RASP (Yu et al., 2010b). Unfortunately, it turned out that one of the errors I got when trying S-Diva was insoluble. Apparently, this error (or any error in RASP for that matter) is quite unique since not a single help forum concerning S-DIVA or RASP is available on the internet. The only available source of help is the manual, where these specific errors are regrettably not addressed.

Then, when I wanted to perform the Bayesian analysis on the full dataset (MAFFT\_8 matrix), I got the message that the maximum number of terminals allowed is 512 while my dataset comprises 568 terminals. In the RASP-manual, it is not specified why there is a maximum limit on the number of terminals and why that number is 512. Since two out of four datasets is larger than is allowed, I pruned the phylogenetic trees to be used for the RASP analysis as well as the corresponding alignment by loading all in Mesquite and deleting terminals with a distribution of more than 6 areas. I preferred this method over removing the taxa from the alignment and rerunning the TNT parsimony analysis, because the original larger number of taxa will provide a better phylogenetic result.

Also, when performing any type of Bayesian analysis, it is desirable to check the parameter (.p) files if the analysis has run long enough. RASP itself did not allow the .p files to be opened, and Tracer (normally used to open the files obtained with MrBayes or Beast, (Rambaut & Drummond, 2007)) was not able to open them. This is quite inconvenient, because there is no way of knowing whether the analyses I run with BBM have a sufficient number of generations. This can have influenced the outcome considerably.

Last, when the analysis finishes, a colour coded legend with all possible area combinations is provided. You then have to check which of the eight shades of light green is the one corresponding to the colour in the pie chart in the topology. Of course this is quite an inconvenience, and brings a huge amount of inaccuracy to the interpretation of the results.

#### 4.4 GENERAL COMMENTS

As explained above, I chose to perform the phylogenetic analysis at the species level while using genus level distribution data for the historical biogeographical analysis. This could be a possible source of bias,

FIGURE 8. IMAGINARY CLADE WITH TAXA A, B, C, D, E.

for example when the terminals belonging to the same genus do not form a monophyletic clade.

In Figure 8 for example, all terminals belonging to the same genus with distribution 1, 2 would be the ideal situation. Then, there is no doubt what the ancestral area would be. If, however, terminals A, B, D and E would belong to the one genus (with distribution 1, 2) while misplaced terminal C belongs to another genus (with distribution 3), this terminal causes a bias in the analysis because this single area skews the biogeographical analysis. In this project this is a serious problem because a lot of the genera turned out non-monophyletic as explained above (Phylogenetic analysis section of this chapter). Especially with wide-spread species (when terminal C has a distribution of 2, 3, 4, 5) this is a substantial problem, because with one terminal the possible ancestral area

range of the clade is dramatically widened. This is one of the reasons why I chose to perform additional biogeographical analysis without the widespread terminals. Another scenario where terminal C would provide a problem is when it has a distribution of 4, 5. In that case, the one terminal also substantially increases areas possible for the ancestral node.

In an ideal world, I would have had a matrix comprising all species of all genera now considered part of the Brassicaceae. With such a complete dataset, it would have been a lot easier to confidently determine the ancestral area of this comprehensive family. In an ideal world, I would also have been able to perform a dating analysis on the phylogenetic tree. We now have an indication of the ancestral area of the Brassicaceae, but it would be helpful if we would be able to place this in a historical context.

## ACKNOWLEDGEMENTS

Without the constant support of both my supervisors, Setareh Mohammadin and Freek T. Bakker, it would not have been possible to complete this project in such a happy and stress-free manner; thank you both for that! In addition, I want to thank Lars Chatrou for his help and guidance during the past week and a half of this thesis. Your critical view and dissecting of my thesis have definately helped me a lot in improving it and keepin on thinking further. In addition, I want to thank all staff and students of the Biosystematics group for a wonderful 6 months.

## APPENDIX C. PHYLOGENETIC TREES

Colour indicates lineage: Lineage I: red; Lineage II: purple; Extended Lineage II: green; and Lineage III: blue.

## 1. RAXML BOOTSTRAP MAFFT – EIGHT GENES

2. RAXML BOOTSTRAP MAFFT – FOUR GENES

3. RAXML BOOTSTRAP MAFFT\_SLOW – EIGHT GENES

4. RAXML BOOTSTRAP MAFFT\_SLOW – FOUR GENES

5. TNT SECTORIAL & RATCHET MAFFT – EIGHT GENES

## 6. TNT SECTORIAL & RATCHET MAFFT – FOUR GENES

## 7. TNT SECTORIAL & RATCHET MAFFT\_SLOW – EIGHT GENES

## 8. TNT SECTORIAL & RATCHET MAFFT\_SLOW – FOUR GENES

9. NEIGHBOUR NETWORK GTR+GAMMA MAFFT – EIGHT GENES

## 10. NEIGHBOUR NETWORK GTR+GAMMA MAFFT – FOUR GENES

# 11. NEIGHBOUR NETWORK GTR+GAMMA MAFFT\_SLOW – EIGHT GENES

## 12. NEIGHBOUR NETWORK GTR+GAMMA MAFFT\_SLOW – FOUR GENES
